I. Summary

The development of efficient and safe conventional (i.e., nonnuclear) propellants and/or fuels is a goal of obvious technological significance. A desirable quality of such a propellant is clearly a high ratio of energy release to mass. The present hypothesis rests on a simple, but previously unrecognized, analogy between oxygen and sulfur. Preliminary studies showed that the oxygen ring systems are sufficiently promising to warrant the detailed, high-level theoretical research reported here.

Our idea begins with the observation that elemental sulfur exists as sulfur rings, S_n . The essence of our proposal is to make an analogy between sulfur rings and oxygen rings. Given the remarkable stability of sulfur rings, should it not be possible to prepare oxygen rings? Oxygen lies directly above sulfur in the Periodic Table, and the analogy is an appealing one.

Work completed includes our study of the prospective HEDM material C₂H₂Li₂. This molecule has been of sustained intellectual interest since 1976 when Paul Schleyer and John Pople suggested that the lowest triplet state of 1,1 -diliythioethylene might allow nearly free rotation about the supposed classical C=C "double bond". In 1985 Manceron

and Andrews intercepted dilithioethylene via matrix isolation infrared spectroscopy in the laboratory. Moreover, in 1987 Maercker, Graule, and Demuth used mercury precursors to characterize *cis* and *trans* 1,2-dilithioethylene as more conventional reaction products. So this species is by no means simply a figment of the theorist's imagination.

The work I describe was published in the *Journal of the American Chemical Society*, having been carried out jointly with the Proctor and Gamble Company. The bulk of the research was carried out by my graduate student Evan Bolton, supported by the AASERT program.

The potential energy surface (PES) for the singlet 1,2-dilithioethene and acetylenic C₂H₂Li₂ isomers was carefully surveyed using high level quantum mechanical methods. Three previously undiscovered minima (including, remarkably, the global minimum) were located: a planar monobridged trans 1,2 dilithioethene and two acetylenic structures. A total of seven minima and ten transition states for interconversion of minima were investigated, while seven transition states are located for the first time. Vibrational frequencies were evaluated for all structures through the coupled-cluster method including all single and double excitation with a double- ζ plus polarization basis set. A remarkable isomer, the Cs complex between lithioacetylene and LiH, is the global minimum on the C₂H₂Li₂ PES. This structure was 34 kcal/mol more stable than the two lowest lying singlet 1,2-dilithioethene structures, a trans planar C_{2h} form with acute CCLi angles and a \emph{cis} doubly bridged C_{2v} structure . The other singlet 1,2-dilithioethene minima , \emph{cis} planar monobridged C_s , cis planar dibridged C_{2v} , and trans planar monobridged C_s , are 4.3, 8.4, and 19.4 kcal/mol higher lying, respectively. The carbon-lithium bonding is ionic in character in all these species.

Another important study has been carried out by graduate student John Galbraith and published recently in the Journal of the American Chemical Society. Motivated by the recent isolation and spectroscopic characterization of nitrosyl azide (N₄O), we have undertaken an ab initio investigation of the originally reported structure as well as various structural isomers on the potential energy hypersurface. Geometries and harmonic vibrational frequencies have been predicted for the trans-chain isomer, along with the 6 π -electron potentially aromatic ring structure, with various levels of theory up through the triple- ζ plus double polarization single and double excitation coupled cluster (TZ2P CCSD) method and the multi-reference configuration interaction method (MRCISD). In addition, estimates are made for extension to higher levels of theory, arriving at final structural predictions for the trans-chain and ring isomers. Energy relationships, bond lengths, vibrational frequencies, Mulliken bond indices, and molecular orbital arguments are used to elucidate the nitrogen oxide bonding. While the ring isomer is predicted to be the most stable structure on the hypersurface, the barrier to dissociation is most likely between 1 and 2 kcal mol-1 (including zero point vibrational energy [ZPVE] the existence of any barrier becomes questionable), making isolation theoretically possible but experimentally difficult. This small barrier also detracts from the attractiveness of the N₄O ring structure as a high energy-density material. The trans-chain isomer, however, lies in an energy valley with higher sides, consistent with its experimental observation.
